Editorial

Postoperative dropping of the nasal tip after rhinoplasty is a known complication.1 Defining the position of the nasal tip begins with stabilizing the nasal base.2 To define the position of the nasal tip and stabilize the nasal base of the nose, the surgeon has three main options: tongue-in-groove maneuver,3 caudal septal extension graft, or columellar strut.4

Significant loss of rotation is expected during the first year and surgeons need to over-correct tip rotation to compensate for this loss. In a recent study, Antunes and Quatela5 identified patients who were submitted to a rhinoplasty with a tongue-in-groove maneuver over a period of 1 year, and demonstrated an average reduction in the nasolabial angle of 6.8%, estimating that for each degree of rotation changed at surgery, the patient will have a loss of 0.35 degrees over the first year.

Despite the routine use of techniques to structure the nasal tip in rhinoplasties, we have observed an increase in the incidence of nasal tip fall in patients who underwent functional and aesthetic rhinoplasty before the covid 19 pandemic and who are now carrying out the 6-month postoperative evaluation.

We selected the last 20 patients who underwent rhinoplasty in the months of November and December 2019 and compared the measurements of the nasolabial angle immediately after surgery and 6 months after surgery. We observed that 14 patients (70%) showed a decrease between 10 and 15 degrees in the nasolabial angle 6 months after surgery, which is not consistent with our results observed over the past years (unpublished).

To date, we do not know published data on nasal ptosis after rhinoplasty due to the excessive use of masks. We are concerned that there may be a progressive increase in the severity of these
cases due to the routine use of masks and the need for even greater support of the nasal tip in patients who will undergo rhinoplasty in the future, believing that wearing masks can become a new habit in patients’ lives.
